**Fecal Dx™ antigen testing—find parasite infections the microscope misses**

**Introduction**

In order to ensure the health of patients, a fecal examination for intestinal parasites is an important part of a regular checkup. Regardless of the fecal procedure used, there can be some limitations on accurately identifying infections with some parasites. Detection of hookworm, roundworm, and whipworm can be difficult with the current diagnostics. IDEXX Reference Laboratories offers Fecal Dx™ antigen testing as an additional tool for detecting these common parasites.

**Background**

In small-animal practice, hookworms, roundworms, and whipworms are commonly encountered intestinal parasites in canine and feline patients. They each have a unique life cycle, and their prepatent period, the time in which they infect a host before laying eggs, may range from 14–21 days in hookworms, 14–30 days in roundworms, to as long as 74–90 days in whipworms. This prepatent period may allow infections to go undetected on microscopic examination, increasing the chance for the appearance of clinical signs prior to evidence of eggs in the stool.

**Prevalence**

In dogs and cats, the prevalence of infection with each intestinal parasite varies from region to region and tends to occur more frequently in shelter animals than in well-cared-for dogs and cats that visit the veterinarian on a regular basis. Outdoor pets and those that consume prey with possible infective larvae in their tissues are also more likely to be infected.

Studies have shown that hookworm and roundworm prevalence in pet dogs was 2.5% and 2.2% respectively and 20.2% and 15.2% in shelter dogs. One study of approximately 1,500 feline fecal specimens found that 7.5% of the cats were shown to be infected with *Toxocara cati*.

The whipworm prevalence in dogs in the U.S., based on detection of eggs in feces, ranges from 1.2% in pet dogs to 14.3% in shelter dogs. In North America, whipworm infections in cats are rare.

**Clinical signs**

Some dogs and cats infected with these common intestinal parasites may be asymptomatic, but others may develop a variety of gastrointestinal signs that depend on the parasite and age of the patient. Symptoms may range from mild diarrhea, vomiting, and ill thrift to severe bloody diarrhea, anemia, and occasionally death.

**Current diagnostics**

Currently, the most common method for diagnosing intestinal parasite infections is microscopic identification (fecal ova & parasites) by passive flotation, flotation by zinc sulfate centrifugation or sedimentation concentration methods. There are many issues that may complicate the diagnosis of infections with this method. One possible complication is misidentification. Pollen and other debris may be misidentified as eggs. In addition, the inappropriate identification of eggs from other species as a result of coprophagy (the ingestion of infected feces) may also occur.

One study researching this occurrence found that 31.5% *Toxocara*-positive canine fecal specimens were in fact *T. cati* eggs.

Another common problem concerns the varying density of the different eggs, which makes it difficult for a clinician to select the ideal fecal processing solution to ensure adequate recovery of eggs from all potential parasites.

Yet another challenge with microscopic identification methods is that these methods of egg identification lack the ability to detect infections during the prepatent period or with single-sex infections, when eggs are simply not present in the infected animal.

Finally, microscopic examination methods may not always be reliable as a single test. Because many parasites shed eggs intermittently, a specimen from an infected animal may still generate a false-negative diagnosis if only a single specimen is examined. For all these reasons, there is a need to find a better tool for the diagnosis of the most common intestinal parasites found in dogs and cats.

**New testing options from IDEXX Reference Laboratories**

Antigen detection is commonly used today to diagnose heartworm and *Giardia* infections, and now it is available for these additional parasites. IDEXX Reference Laboratories has developed Fecal Dx antigen testing, which includes enzyme-linked immunosorbent assays (ELISAs) for the detection of hookworm, roundworm, and whipworm antigens in feces. These antigens are secreted by the adult worm and are not present in their eggs, which allows for detection of prepatent stages as well as the ability to overcome the challenges of intermittent egg laying. This early detection during the prepatent period will also reduce the frequency of environmental contamination with potentially infectious eggs. As recommended by the Companion Animal Parasite Council (CAPC), fecal tests for antigen should be combined with microscopic examination of feces for eggs for the widest breadth of detection of intestinal parasites in dogs and cats.

**Detect more infections**

More than 750,000 IDEXX Reference Laboratories fecal results, consisting of both canine and feline specimens, were analyzed for positive nematode results. These specimens were submitted for testing using both microscopic identification (fecal flotation by zinc sulfate centrifugation) and fecal antigen ELISA methods for hookworm, roundworm, and whipworm.

Hookworm eggs were detected in 1.7% of the specimens. The hookworm-specific antigen ELISA was positive in an additional 2.0% of specimens that were negative for hookworm eggs, thus bringing the total hookworm detection with the combined fecal O&P and antigen ELISA testing to 3.7%.

Roundworm (ascarid) eggs were detected in 2.2% of the specimens. The roundworm-specific antigen ELISA was positive in an additional 1.3% of specimens that were negative for roundworm (ascarid) eggs, thus bringing the total roundworm detection with the combined fecal O&P and antigen ELISA testing to 3.5%.
Whipworm eggs were detected in 0.7% of the canine specimens. The whipworm-specific antigen ELISA was positive in an additional 1.0% of specimens that were negative for whipworm eggs by fecal O&P testing, thus bringing the total whipworm detection with the combined fecal O&P and antigen ELISA testing to 1.7%.

**Intestinal parasite detection**

Because of the lack of egg detection with fecal O&P testing during the prepatent period and single-sex infections, many parasite infections may go undetected for a period of time and, therefore, create a difficulty in correlating clinical signs to fecal test results. In an experimental infection study conducted at IDEXX, the fecal antigen ELISAs were able to detect infection during this prepatent stage.

The graph below illustrates the identification of a whipworm infection approximately 30 days before fecal O&P testing when using the whipworm-specific antigen ELISA.

**Public health considerations and preventive measures**

Because of the zoonotic potential of these parasites, most commonly hookworm and roundworm, immediate disposal of feces is important. This will also reduce the likelihood of reinfections and prevent the long-term contamination of the environment. Monthly anthelmintic medications can be helpful in preventing the continuation of the cycle.

**Detect infections earlier**

Because of the lack of egg detection with fecal O&P testing during the prepatent period and single-sex infections, many parasite infections may go undetected for a period of time and, therefore, create a difficulty in correlating clinical signs to fecal test results. In an experimental infection study conducted at IDEXX, the fecal antigen ELISAs were able to detect infection during this prepatent stage.

The graph below illustrates the identification of a whipworm infection approximately 30 days before fecal O&P testing when using the whipworm-specific antigen ELISA.

**Prepatent infection detection**

**Treatment**

There are a variety of anthelmintic products available for both treatment and control of hookworm, roundworm, and whipworm infections. Please see the current Companion Animal Parasite Council (CAPC) recommendations for guidance.

Fecal Dx™ antigen testing detects worm antigen. A positive antigen test indicates infection. Antigen-positive and egg-negative specimens can be seen during the prepatent period, with single-sex infections, and as a result of intermittent egg shedding. Microscopic identification of eggs in antigen-negative specimens may be due to coprophagy or because the amount of antigen is below the level of detection. Treatment should be considered for patients found positive by either antigen or egg detection.

**Contacting IDEXX**

**Laboratory Customer Support**

If you have any questions regarding test codes, turnaround time, or pricing, please contact our Laboratory Customer Support Team at 1-800-667-3411, option 1, option 1.

**Expert feedback when you need it**

Our medical specialty consulting service is available for expert and complimentary consultation. Please call 1-800-667-3411, option 1, option 3 if you have questions.
